Abstract

This paper presents the MATLAB package **DeCo** (density combination) which is based on the paper by [Billio, Casarin, Ravazzolo, and van Dijk \(2013\)](#) where a constructive Bayesian approach is presented for combining predictive densities originating from different models or other sources of information. The combination weights are time-varying and may depend on past predictive forecasting performances and other learning mechanisms. The core algorithm is the function **DeCo** which applies banks of parallel sequential Monte Carlo algorithms to filter the time-varying combination weights. The **DeCo** procedure has been implemented both for standard CPU computing and for graphical process unit (GPU) parallel computing. For the GPU implementation we use the MATLAB parallel computing toolbox and show how to use general purpose GPU computing almost effortlessly. This GPU implementation provides a speed-up of the execution time of up to seventy times on a standard CPU MATLAB implementation on a multicore CPU. We show the use of the package and the computational gain of the GPU version through some simulation experiments and empirical applications.

Keywords: density forecast combination, sequential Monte Carlo, parallel computing, GPU, MATLAB.

1. Introduction

Combining forecasts from different statistical models or other sources of information is a crucial issue in many different fields of science. Several papers have been proposed to handle this issue with [Bates and Granger \(1969\)](#) being one of the first attempts in this field. Initially

the focus was on defining and estimating combination weights for point forecasting. For instance, [Granger and Ramanathan \(1984\)](#) propose to combine forecasts with unrestricted least squares regression coefficients as weights. [Terui and van Dijk \(2002\)](#) generalize least squares weights by specifying the weights in the dynamic forecast combination as a state space model with time-varying weights that are assumed to follow a random walk process. Recently, research interest has shifted to the construction of combinations of predictive densities (and not point forecasts) as well as allowing for model set incompleteness (the true model may not be included in the set of models for prediction) and learning. Further, different model evaluation criteria are used. [Hall and Mitchell \(2007\)](#) and [Geweke and Amisano \(2010\)](#) propose using combination schemes based on the Kullback-Leibler score; [Gneiting and Raftery \(2007\)](#) recommend strictly proper scoring rules, such as the cumulative rank probability score, in particular, if the focus is on some particular area, such as extreme tails, of the distribution. [Billio et al. \(2013\)](#) (hereby BCRVD 2013) provide a general Bayesian distributional state space representation of predictive densities and specify combination schemes that allow for an incomplete set of models and different learning mechanisms and scoring rules.

The design of algorithms for a numerically efficient combination remains a challenging issue (e.g., see [Gneiting and Raftery 2007](#)). BCRVD (2013) propose a combination algorithm based on sequential Monte Carlo filtering. The proposed algorithm makes use of a random grid from the set of predictive densities and runs a particle filter at each point of the grid. The procedure is computationally intensive when the number of models to combine increases. A contribution of this paper is to present a MATLAB (see [The MathWorks Inc. 2011](#)) package **DeCo** (density combination) for the combination of predictive densities and a simple graphical user interface (GUI) for the use of this package.

This paper provides, through the **DeCo** package, an efficient implementation of the BCRVD (2013) algorithm based on central processing unit (CPU) and graphics processing unit (GPU) parallel computing. We make use of recent increases in computing power and recent advances in parallel programming techniques. The focus of the microprocessor industry, mainly driven by Intel and AMD, has shifted from maximizing the performance of a single core to integrating multiple cores in one chip, see [Sutter \(2005\)](#) and [Sutter \(2011\)](#). Contemporaneously, the needs of the video game industry, requiring increasing computational performance, boosted the development of the GPU, which enabled massively parallel computation.

In the present paper, we follow the recent trend of using GPUs for general, non-graphics, applications (prominently featuring those in scientific computing), the so-called general-purpose computing on graphics processing unit (GPGPU) approach. The GPGPU approach has been applied successfully in different fields such as astrophysics, biology, engineering, and finance, where quantitative analysts started using this technology well ahead of academic economists, see [Morozov and Mathur \(2012\)](#) for a literature review.

To date, the adoption of GPU computing technology in economics and econometrics has been relatively slow compared with other fields. There are a few papers that deal with this interesting topic, see [Suchard, Holmes, and West \(2010\)](#), [Morozov and Mathur \(2012\)](#), [Aldrich, Fernández-Villaverde, Gallant, and Ramirez \(2011\)](#), [Durham and Geweke \(2014\)](#), [Dziubinski and Grassi \(2014\)](#) and [Creel, Mandal, and Zubair \(2012\)](#). This is odd given the fact that parallel computing in economics has a long history. An early attempt to use parallel computation for Monte Carlo simulation is [Chong and Hendry \(1986\)](#), while [Swann \(2002\)](#) develops a parallel implementation of maximum likelihood estimation. [Creel and Goffe \(2008\)](#) discuss a number of economic and econometric problems where parallel computing can be applied. The

	Advantages	Disadvantages
CUDA	Free	Vendor lock-in
OpenCL	Free Heterogeneous	Difficult to program
Thrust	Free Easy to program	Vendor lock-in
C++ AMP	Open Standard Heterogeneous Free (Express Edition) Easy to program	Currently only Windows implementations exist

Table 1: Comparison of different currently available GPGPU approaches.

low diffusion of this technology in economics and econometrics, according to [Creel \(2005\)](#), is mainly due to two issues, which are the high cost of the hardware, e.g., a computing cluster, and the steep learning curve of dedicated programming languages such as CUDA (compute unified device architecture, see [NVIDIA Corporation 2010](#)), OpenCL ([Khronos OpenCL Working Group 2009](#)), Thrust ([Hoberock and Bell 2011](#)) and C++ AMP (C++ accelerated massive parallelism, see [Gregory and Miller 2012](#)). Table 1 compares different currently available GPGPU approaches. The recent increase in attention to parallel computing is motivated by the fact that the hardware costs issue has been solved by the introduction of modern GPUs with relatively low cost. Nevertheless, the second issue remains open. For example, [Lee, Christopher, Giles, Doucet, and Holmes \(2010\)](#) report that a programmer proficient in C ([Press, Teukolsky, Vetterling, and Flannery 1992](#)) or C++ ([Stroustrup 2000](#)), a programming skill that can take some time to be acquired, should be able to code effectively in CUDA within a few weeks.

We aim to contribute to this stream of literature by showing that GPU computing can be carried out almost without any extra effort using the parallel toolbox of MATLAB (available in version 2012b and following releases, see [The MathWorks Inc. 2011](#)) and a suitable approach to MATLAB coding of the algorithms. The MATLAB environment allows easy use of GPU programming without learning CUDA. We emphasize that this paper is not intended to compare CPU and GPU computing. In fact, we propose the combination algorithm for both standard parallel CPU and for parallel GPU computation. Our simulation and empirical experiments show that the **DeCo** GPU version is faster 3 to 10 times than the parallel multi-core CPU version, similar to recommendations in [Brodtkorb, Hagen, and Sætra \(2013\)](#), and up to 70 times faster than the standard sequential CPU version.

The structure of the paper is as follows. Section 2 introduces the principles of density forecast combinations with time-varying weights and parallel sequential Monte Carlo algorithms. Section 3 presents a parallel sequential Monte Carlo algorithm for density combinations. It also provides background material on GPU computing in MATLAB. Section 4 carries out a comparison, using a Monte Carlo simulation, between CPU and GPU calculation. Section 5 reports the results for the macroeconomic empirical application. Section 6 concludes. Appendix A describes the structure of the algorithm, Appendix B shows the package GUI and Appendix C illustrates the corresponding MATLAB functions with the input and output description.

2. Time-varying combinations of predictive densities

2.1. A combination scheme

BCRVD (2013) introduced a general scheme for combining predictive densities, which allows for time-varying weights for the different densities; model set incompleteness (meaning the true model might not be in the model set); combination weight uncertainty and learning, in order to achieve more accurate forecasts. The authors present a distributional state space representation of the combination scheme, provide an effective algorithm for the sequential estimation of the combination weights and discuss some alternative specifications of the combination and of weight dynamics.

In order to make the present paper self-contained, we summarize the essential idea of the approach here, where we note that, for simplicity, we apply the Gaussian combination scheme with logistic weights. For more details and alternatives we refer to BCRVD (2013).

Denote with $\mathbf{v}_{1:t} = (\mathbf{v}_1, \dots, \mathbf{v}_t)$ a collection of vectors \mathbf{v}_s with $s = 1, \dots, t$. Let $\mathbf{y}_t \in \mathcal{Y} \subset \mathbb{R}^L$ be the L -vector of observable variables at time t and $\tilde{\mathbf{y}}_t = (\tilde{\mathbf{y}}_{1,t}^\top, \dots, \tilde{\mathbf{y}}_{K,t}^\top)^\top \in \mathcal{Y}^K \subset \mathbb{R}^{KL}$, with element $\tilde{\mathbf{y}}_{k,t} = (\tilde{y}_{k,t}^1, \dots, \tilde{y}_{k,t}^L)^\top \in \mathcal{Y} \subset \mathbb{R}^L$ the typical one-step-ahead predictor for \mathbf{y}_t for the k th model, $k = 1, \dots, K$, in the pool, with predictive density $p(\tilde{\mathbf{y}}_{k,t} | \mathbf{y}_{1:t-1}, \mathcal{I}_k)$, where $\mathbf{y}_{1:t-1}$ refers to the past information on the relevant variable and \mathcal{I}_k refers to the structural information set for the k th model, $k = 1, \dots, K$.

Basically, the combined density is the marginal density of the joint density of observed variables, latent weights and predicted variables of K models integrated, otherwise stated marginalized, with respect to the latent weights and the predicted variables from the K models. More specifically, the combined density of the observed \mathbf{y}_t given the past data values and the structural specifications of all models is given as

$$p(\mathbf{y}_t | \mathbf{y}_{1:t-1}, \mathcal{I}_K) = \int_{\mathcal{Y}^{Kt}} \int_{\mathcal{W}} p(\mathbf{y}_t, W_t, \tilde{\mathbf{y}}_{1:t} | \mathbf{y}_{1:t-1}, \mathcal{I}_K) dW_t d\tilde{\mathbf{y}}_{1:t}, \quad (1)$$

where $W_t = (\mathbf{w}_t^1, \dots, \mathbf{w}_t^L)^\top \in \mathcal{W} \subset \mathbb{R}^{L \times KL}$ is a weight matrix, with $\mathbf{w}_t^l = (w_{1,t}^l, \dots, w_{KL,t}^l)^\top$ as the l th row vector containing the combination weights for the KL elements of $\tilde{\mathbf{y}}_t$.

The joint density, given in (1), can be rewritten as the product of three conditional densities

$$p(\mathbf{y}_t, W_t, \tilde{\mathbf{y}}_{1:t} | \mathbf{y}_{1:t-1}, \mathcal{I}_K) = p(\mathbf{y}_t | W_t, \tilde{\mathbf{y}}_{1:t}, \mathbf{y}_{1:t-1}, \mathcal{I}_K) p(W_t | \tilde{\mathbf{y}}_{1:t}, \mathbf{y}_{1:t-1}, \mathcal{I}_K) p(\tilde{\mathbf{y}}_{1:t} | \mathbf{y}_{1:t-1}, \mathcal{I}_K),$$

where the conditional density $p(\mathbf{y}_t | W_t, \tilde{\mathbf{y}}_{1:t}, \mathbf{y}_{1:t-1}, \mathcal{I}_K)$ specifies the particular combination that is used, $p(W_t | \tilde{\mathbf{y}}_{1:t}, \mathbf{y}_{1:t-1}, \mathcal{I}_K)$ is the conditional density of the K latent weights and $p(\tilde{\mathbf{y}}_{1:t} | \mathbf{y}_{1:t-1}, \mathcal{I}_K)$ is the conditional predictive density for the predicted variables $\tilde{\mathbf{y}}_{1:t}$ given the past data information and the structural information, $\mathcal{I}_K = \bigvee_{k=1}^K \mathcal{I}_k$, on the K models. In this paper, the joint density of the predictor is defined as

$$p(\tilde{\mathbf{y}}_{t+1} | \mathbf{y}_{1:t}, \mathcal{I}_K) = \prod_{k=1}^K p(\tilde{\mathbf{y}}_{k,t+1} | \mathbf{y}_{1:t}, \mathcal{I}_k). \quad (2)$$

Note that if each of these densities was a member of the family of normal densities, the multiple integral in (1) can be evaluated analytically.

In our case the density of the particular combination is given as a Gaussian density that allows for model incompleteness

$$p(\mathbf{y}_t | W_t, \tilde{\mathbf{y}}_t, \mathcal{I}_K) \propto |\Sigma|^{-\frac{1}{2}} \exp \left\{ -\frac{1}{2} (\mathbf{y}_t - W_t \tilde{\mathbf{y}}_t)^\top \Sigma^{-1} (\mathbf{y}_t - W_t \tilde{\mathbf{y}}_t) \right\} \quad (3)$$

$t = 1, \dots, T$. We assume for the present paper that the covariance matrix, i.e., $\Sigma = \text{diag}\{\sigma_1^2, \dots, \sigma_L^2\}$ is diagonal. We emphasize that the disturbances in the combination density and their variances give important signals on model incompleteness. That is, the combination model can be re-written as

$$\mathbf{y}_t = W_t \tilde{\mathbf{y}}_t + \zeta_t \quad (4)$$

with $\zeta_t \stackrel{\text{i.i.d.}}{\sim} \mathcal{N}(0, \Sigma)$.

With respect to the specification of the latent weights $w_{h,t}^l$ we assume these to be nonlinear transformations of latent variables $x_{h,t}^l$ given as

$$w_{h,t}^l = \frac{\exp\{x_{h,t}^l\}}{\sum_{j=1}^{KL} \exp\{x_{j,t}^l\}}, \quad \text{with } h = 1, \dots, KL \quad (5)$$

This change of variables allows us to define a new latent matrix $X_t = (\mathbf{x}_t^1, \dots, \mathbf{x}_t^L)^\top$ with density $p(X_t | \tilde{\mathbf{y}}_{1:t}, \mathbf{y}_{1:t-1}, \mathcal{I}_K)$. We further assume a transition density that allows the weights and the latent variable X_t to have a first-order Markovian structure and to let them possibly depend on past values of the observed and predicted values of \mathbf{y}_t . That is,

$$p(\mathbf{x}_t | \mathbf{x}_{t-1}, \mathcal{I}_K) \propto |\Lambda|^{-\frac{1}{2}} \exp \left\{ -\frac{1}{2} (\mathbf{x}_t - \mathbf{x}_{t-1})^\top \Lambda^{-1} (\mathbf{x}_t - \mathbf{x}_{t-1}) \right\} \quad (6)$$

with $\mathbf{x}_t = \text{vec}(X_t) \in \mathcal{X} \subset \mathbb{R}^{KL^2}$. We assume the covariance matrix of the so-called state noise is diagonal, i.e., $\Lambda = \text{diag}\{\lambda_1, \dots, \lambda_{KL^2}\}$. A learning mechanism can also be added to the weight dynamics, resulting in

$$p(\mathbf{x}_t | \mathbf{x}_{t-1}, \mathbf{y}_{t-\tau:t-1}, \tilde{\mathbf{y}}_{t-\tau:t-1}, \mathcal{I}_K) \propto |\Lambda|^{-\frac{1}{2}} \exp \left\{ -\frac{1}{2} (\mathbf{x}_t - \boldsymbol{\mu}_t)^\top \Lambda^{-1} (\mathbf{x}_t - \boldsymbol{\mu}_t) \right\}, \quad (7)$$

where $\boldsymbol{\mu}_t = \mathbf{x}_{t-1} - \Delta \mathbf{e}_t$, $\Delta \mathbf{e}_t = (\mathbf{e}_t - \mathbf{e}_{t-1})$ and elements of \mathbf{e}_t

$$e_{K(l-1)+k,t}^l = (1 - \lambda) \sum_{i=1}^{\tau} \lambda^{i-1} f(y_{t-i}^l, \tilde{y}_{k,t-i}^l),$$

$k = 1, \dots, K$, $l = 1, \dots, L$, with $\lambda \in [0, 1]$ a discount factor and τ the number of previous observations used in the learning. We assume the function $f()$ defines a learning strategy. Note that the **DeCo** package relies on a general algorithm which can account for different scoring rules, such as the Kullback-Leibler score (Hall and Mitchell 2007 and Geweke and Amisano 2010) and the cumulative rank probability score (Gneiting and Raftery 2007).¹

For the predictive density $p(\tilde{\mathbf{y}}_{1:t} | \mathbf{y}_{1:t-1}, \mathcal{I}_K)$ one can make use of different approaches to estimate these equations and generate predicted values (e.g., see Casarin, Chang, Jimenez-Martin,

¹The user interested in different scoring rules should change the command lines with the learning in the file `PFCoreGPU.m` for the GPU version and `PFCore.m` for the CPU version.

McAleer, and Amaral 2013 and Aastveit, Ravazzolo, and van Dijk 2014). In the present paper we assume that these predicted values have been generated by a Bayesian procedure.

2.2. State space representation of the combination scheme

The combination scheme, given in Section 2.1, can be restated in a nonlinear state space representation where an efficient algorithm can be applied to solve for the integration problem. The proposed state space representation is, as usual, composed of an observation equation, given in (3) and a transition equation of the latent weights equations, given in (5), (6) or (7). These provide a forecast density for the observable variables conditional on the predictors. The representation is quite general, allowing for nonlinear and non-Gaussian combination models. In Section 2.3, we specify a sequential Monte Carlo algorithm, also known as a particle filter, to estimate sequentially over time the optimal combination weights and the combination density.

Note that, due to the change of variable in (5), the integral with respect to W_t in (1) can be written as an integral in \mathbf{x}_t and the state space representation can be sketched as follows. Let $\boldsymbol{\theta} \in \Theta \subset \mathbb{R}^{n_\theta}$ be the parameter vector of the combination model, with $\boldsymbol{\theta} = (\log \sigma_1^2, \dots, \log \sigma_L^2, \log \lambda_1, \dots, \log \lambda_{KL^2})$. Define the augmented state space $\mathcal{Z} = \mathcal{X} \times \Theta$ and the augmented state vector $\mathbf{z}_t = (\mathbf{x}_t, \boldsymbol{\theta}_t) \in \mathcal{Z}$, where $\boldsymbol{\theta}_t = \boldsymbol{\theta}$, $\forall t$. The distributional state space form of the forecast model is

$$\mathbf{y}_t \sim p(\mathbf{y}_t | \mathbf{z}_t, \tilde{\mathbf{y}}_t, \mathcal{I}_K) \quad (\text{measurement density}) \quad (8)$$

$$\mathbf{z}_t \sim p(\mathbf{z}_t | \mathbf{z}_{t-1}, \mathbf{y}_{1:t-1}, \tilde{\mathbf{y}}_{1:t-1}, \mathcal{I}_K) \quad (\text{transition density}) \quad (9)$$

$$\mathbf{z}_0 \sim p(\mathbf{z}_0 | \mathcal{I}_K) \quad (\text{initial density}) \quad (10)$$

The state predictive and filtering densities conditional on the predictive variables $\tilde{\mathbf{y}}_{1:t}$ and the structural information \mathcal{I}_K are

$$p(\mathbf{z}_{t+1} | \mathbf{y}_{1:t}, \tilde{\mathbf{y}}_{1:t}, \mathcal{I}_K) = \int_{\mathcal{Z}} p(\mathbf{z}_{t+1} | \mathbf{z}_t, \mathbf{y}_{1:t}, \tilde{\mathbf{y}}_{1:t}, \mathcal{I}_K) p(\mathbf{z}_t | \mathbf{y}_{1:t}, \tilde{\mathbf{y}}_{1:t}, \mathcal{I}_K) d\mathbf{z}_t, \quad (11)$$

$$p(\mathbf{z}_{t+1} | \mathbf{y}_{1:t+1}, \tilde{\mathbf{y}}_{1:t+1}, \mathcal{I}_K) = \frac{p(\mathbf{y}_{t+1} | \mathbf{z}_{t+1}, \tilde{\mathbf{y}}_{t+1}) p(\mathbf{z}_{t+1} | \mathbf{y}_{1:t}, \tilde{\mathbf{y}}_{1:t}, \mathcal{I}_K)}{p(\mathbf{y}_{t+1} | \mathbf{y}_{1:t}, \tilde{\mathbf{y}}_{1:t}, \mathcal{I}_K)}, \quad (12)$$

respectively, which represent the optimal nonlinear filter (see Doucet, Freitas, and Gordon 2001). The marginal predictive density of the observable variables is then

$$p(\mathbf{y}_{t+1} | \mathbf{y}_{1:t}, \mathcal{I}_K) = \int_{\mathcal{Y}} p(\mathbf{y}_{t+1} | \mathbf{y}_{1:t}, \tilde{\mathbf{y}}_{t+1}, \mathcal{I}_K) p(\tilde{\mathbf{y}}_{t+1} | \mathbf{y}_{1:t}, \mathcal{I}_K) d\tilde{\mathbf{y}}_{t+1}, \quad (13)$$

where $p(\mathbf{y}_{t+1} | \mathbf{y}_{1:t}, \tilde{\mathbf{y}}_{t+1}, \mathcal{I}_K)$ is defined as

$$\int_{\mathcal{Z} \times \mathcal{Y}^{K_t}} p(\mathbf{y}_{t+1} | \mathbf{z}_{t+1}, \tilde{\mathbf{y}}_{t+1}, \mathcal{I}_K) p(\mathbf{z}_{t+1} | \mathbf{y}_{1:t}, \tilde{\mathbf{y}}_{1:t}, \mathcal{I}_K) p(\tilde{\mathbf{y}}_{1:t} | \mathbf{y}_{1:t-1}, \mathcal{I}_K) d\mathbf{z}_{t+1} d\tilde{\mathbf{y}}_{1:t} \quad (14)$$

and represents the conditional predictive density of the observable given the past values of the observable and of the predictors. We refer to Aastveit *et al.* (2014) for an application of this approach to the case of nowcasting using dynamic factor models and to Casarin *et al.* (2013) for an application to financial risk measurement using GARCH models.

2.3. A filtering algorithm for the combination state space model

The analytical solution of the optimal filter for nonlinear state space models is generally not known. An approximate solution is needed. We apply a numerical approximation method, which converges to the optimal filter in Hilbert metric, in the total variation norm and in a weaker distance suitable for random probability distributions (e.g., see [Legland and Oudjane 2004](#)). More specifically, we consider a sequential Monte Carlo (SMC) approach to filtering. See [Doucet *et al.* \(2001\)](#) for an introduction to SMC and [Creal \(2009\)](#) for a recent survey on SMC in economics. We propose using banks of SMC filters, where each filter is conditioned on a sequence of realizations of the predictor vector $\tilde{\mathbf{y}}_t$, see BCRVD(2013). The resulting algorithm for the sequential combination of densities is defined through the following steps, see Appendix A for a graphical representation.

Step 0 (Initialization, Equation 10):

Initialize independent particle sets $\Xi_0^j = \{\mathbf{z}_0^{i,j}, \omega_0^{i,j}\}_{i=1}^N$, $j = 1, \dots, M$. Each particle set Ξ_0^j contains N i.i.d. random variables $\mathbf{z}_0^{i,j}$ with random weights $\omega_0^{i,j}$.² Initialize a random grid over the set of predictors, by generating i.i.d. samples $\tilde{\mathbf{y}}_1^j$, $j = 1, \dots, M$, from $p(\tilde{\mathbf{y}}_1|\mathbf{y}_0, \mathcal{I}_K)$. We use the sample of observations \mathbf{y}_0 to initialize the individual predictors.

Step 1 (Predictor generation, Equation 2):

At the iteration $t + 1$ of the combination algorithm, we approximate the predictive density $p(\tilde{\mathbf{y}}_{t+1}|\mathbf{y}_{1:t}, \mathcal{I}_K)$ with the discrete probability

$$p_M(\tilde{\mathbf{y}}_{t+1}|\mathbf{y}_{1:t}, \mathcal{I}_K) = \frac{1}{M} \sum_{j=1}^M \delta_{\tilde{\mathbf{y}}_{t+1}^j}(\tilde{\mathbf{y}}_{t+1}),$$

where $\tilde{\mathbf{y}}_{t+1}^j$, $j = 1, \dots, M$, are i.i.d. samples from the predictive densities and $\delta_x(y)$ denotes the Dirac mass centered at x . This approximation is also motivated by the forecasting practice (see [Jore, Mitchell, and Vahey 2010](#)). The predictions usually come, from different models or sources, in the form of discrete densities. In some cases, this is the result of a collection of point forecasts from many subjects, such as survey forecasts. In other cases the discrete predictive function is a result of a Monte Carlo approximation of the predictive density (e.g., importance sampling or Markov chain Monte Carlo approximation of the model predictive density).

Step 2 (Filtering and prediction):

We assume an independent sequence of particle sets $\Xi_t^j = \{\mathbf{z}_{1:t}^{i,j}, \omega_t^{i,j}\}_{i=1}^N$, $j = 1, \dots, M$, is available at time $t + 1$ and that each particle set provides the approximation

$$p_{N,j}(\mathbf{z}_t|\mathbf{y}_{1:t}, \tilde{\mathbf{y}}_{1:t}^j, \mathcal{I}_K) = \sum_{i=1}^N \omega_t^{i,j} \delta_{\mathbf{z}_t^{i,j}}(\mathbf{z}_t) \quad (15)$$

of the filtering density, $p(\mathbf{z}_t|\mathbf{y}_{1:t}, \tilde{\mathbf{y}}_{1:t}^j, \mathcal{I}_K)$, conditional on the j th predictor realization, $\tilde{\mathbf{y}}_{1:t}^j$. Then M independent SMC algorithms are used to find a new sequence of M particle sets,

²The parameter $\theta_0^{i,j}$ in $\mathbf{z}_0^{i,j}$ can be fixed or estimated. When estimated, the parameter must be initialized by drawing from the prior. The prior requires the specification of the mean and the standard deviation of the random noise of the log normal random walk process that θ is assumed to follow. **DeCo** toolbox includes all these options, see Appendix B.

which include the information available from the new observation and the new predictors. Each SMC algorithm iterates, for $j = 1, \dots, M$, the following steps.

Step 2.a (State prediction, Equation 11):

The basic SMC algorithm uses the particle set to approximate the predictive density with an empirical density. We use a regularized version of the SMC procedure (e.g., see [Liu and West 2001](#), [Musso, Oudjane, and Legland 2001](#) and [Casarin and Marin 2009](#)). More specifically, the predictive density of combination weights and parameters, \mathbf{z}_{t+1} , conditional on $\tilde{\mathbf{y}}_{1:t}^j$ and $\mathbf{y}_{1:t}$ is approximated as follows

$$p_{N,j}(\mathbf{z}_{t+1}|\mathbf{y}_{1:t}, \tilde{\mathbf{y}}_{1:t}^j, \mathcal{I}_K) = \sum_{i=1}^N p(\mathbf{x}_{t+1}|\mathbf{x}_t, \boldsymbol{\theta}_{t+1}, \mathbf{y}_{1:t}, \tilde{\mathbf{y}}_{1:t}^j, \mathcal{I}_K) \omega_t^{i,j} \delta_{\mathbf{x}_t^{i,j}}(\mathbf{x}_t) K_h(\boldsymbol{\theta}_{t+1} - \boldsymbol{\theta}_t^{i,j}), \quad (16)$$

where $K_h(y) = h^{-n_\theta} K(y/h)$ is the regularization kernel, K being a positive function defined on \mathbb{R}^{n_θ} and h a positive smoothing factor (bandwidth).

Step 2.b (State filtering, Equation 12):

We update the state predictive density by using the information coming from $\tilde{\mathbf{y}}_{t+1}^j$ and \mathbf{y}_{t+1} , that is

$$p_{N,j}(\mathbf{z}_{t+1}|\mathbf{y}_{1:t+1}, \tilde{\mathbf{y}}_{1:t+1}^j, \mathcal{I}_K) = \sum_{i=1}^N \gamma_{t+1}^{i,j} \delta_{\mathbf{z}_{t+1}^{i,j}}(\mathbf{z}_{t+1}), \quad (17)$$

where $\gamma_{t+1}^{i,j} \propto \omega_t^{i,j} p(\mathbf{y}_{t+1}|\mathbf{z}_{t+1}^{i,j}, \tilde{\mathbf{y}}_{t+1}^j, \mathcal{I}_K)$ is a set of normalized weights and $\mathbf{z}_{t+1}^{i,j} = (\mathbf{x}_{t+1}^{i,j}, \boldsymbol{\theta}_{t+1}^{i,j})$ with $\boldsymbol{\theta}_{t+1}^{i,j} \sim K_h(\boldsymbol{\theta}_{t+1} - \boldsymbol{\theta}_t^{i,j})$ and $\mathbf{x}_{t+1}^{i,j} \sim p(\mathbf{x}_{t+1}|\mathbf{x}_t, \boldsymbol{\theta}_{t+1}^{i,j}, \mathbf{y}_{1:t}, \tilde{\mathbf{y}}_{1:t}^j, \mathcal{I}_K)$, $i = 1, \dots, N$.

Step 2.c (Observation prediction, Equation 14):

The hidden state predictive density can be used to approximate the observable predictive density as follows

$$p_{N,j}(\mathbf{y}_{t+1}|\mathbf{y}_{1:t}, \tilde{\mathbf{y}}_{1:t+1}^j, \mathcal{I}_K) = \sum_{i=1}^N \gamma_{t+1}^{i,j} \delta_{\mathbf{y}_{t+1}^{i,j}}(\mathbf{y}_{t+1}) \quad (18)$$

where $\mathbf{y}_{t+1}^{i,j}$ has been simulated from the combination model $p(\mathbf{y}_{t+1}|\mathbf{z}_{t+1}^{i,j}, \tilde{\mathbf{y}}_{t+1}^j, \mathcal{I}_K)$ independently for $i = 1, \dots, N$.

Step 2.d (Observation predictive distribution, Equation 14):

The resampling (multinomial resampling) of the particles introduces extra Monte Carlo variations, see [Liu and Chen \(1998\)](#). This can be reduced by doing resampling only when the effective sample size (ESS) is below a given threshold. The ESS is defined as

$$\text{ESS}_t^j = \frac{N}{1 + N \sum_{i=1}^N \left(\gamma_{t+1}^{i,j} - N^{-1} \sum_{i=1}^N \gamma_{t+1}^{i,j} \right)^2 / \left(\sum_{i=1}^N \gamma_{t+1}^{i,j} \right)^2}$$

and measures the overall efficiency of an importance sampling algorithm. At the $t+1$ th iteration if $\text{ESS}_{t+1}^j < \kappa$, simulate $\Xi_{t+1}^j = \{\mathbf{z}_{t+1}^{k_i,j}, \omega_{t+1}^{i,j}\}_{i=1}^N$ from $\{\mathbf{z}_{t+1}^{i,j}, \gamma_{t+1}^{i,j}\}_{i=1}^N$ (e.g., multinomial resampling) and set $\omega_{t+1}^{i,j} = 1/N$. We denote with k_i the index of the i th re-sampled particle in the original set Ξ_{t+1}^j . If $\text{ESS}_{t+1}^j \geq \kappa$ set $\Xi_{t+1}^j = \{\mathbf{z}_{t+1}^{i,j}, \omega_{t+1}^{i,j}\}_{i=1}^N$.

Step 3 (Observation marginal predictive, Equation 13):

At the last step, obtain the following empirical predictive density

$$p_{M,N}(\mathbf{y}_{t+1}|\mathbf{y}_{1:t},\mathcal{I}_K) = \frac{1}{M} \sum_{j=1}^M \sum_{i=1}^N \omega_{t+1}^{i,j} \delta_{\mathbf{y}_{t+1}^{i,j}}(\mathbf{y}_{t+1}). \quad (19)$$

The precision of our numerical approximation method depends on the choice of M and N . As regards the precision of the combination weight estimates, it can be increased by setting a larger N . The approximation of the forecasting densities can be increased choosing a larger M . Notice that the choice of M does not affect the convergence of the particle filter algorithms, which depends only on the choice of N . The assumptions required for convergence of the SMC algorithms are discussed in, e.g., [Moral and Guionnet \(2001\)](#) and [Gland and Oudjane \(2004\)](#) for regularized particle filters. Central limit theorems for particle filters can be found in [Chan and Lai \(2013\)](#) and [Chopin \(2004\)](#).

3. Parallel SMC for density combination: DeCo

MATLAB is a popular software in the economics and econometrics community (e.g., see [LeSage 1998](#)), which has recently introduced support for GPU computing in its parallel computing toolbox. This allows the use of raw CUDA code within a MATLAB program as well as already built-in functions that are directly executed on the GPU. Using the built-in functions we show that the GPGPU approach can be almost effortlessly implemented with the only required knowledge being decent MATLAB programming skills. With a little effort we provide a GPU implementation of the methodology recently proposed by [BCRVD \(2013\)](#). This implementation provides a speed-up of the execution time of up to a hundred times on a multicore CPU with a standard MATLAB code.

3.1. GPU computing in MATLAB

There is little difference between the CPU and GPU MATLAB code: Listings 1 and 2 report the same program which generates and inverts a matrix on CPU and GPU respectively.

The GPU code, Listing 2, uses the command `gpuArray.randn` to generate a matrix of normal random numbers. The built-in function `gpuArray.randn` is handled by the NVIDIA plug-in

```

1 iRows = 1000; iColumns = 1000; % Number of rows and columns
2 C_on_CPU = randn(iRows, iColumns); % Generate random number on the CPU
3 InvC_on_CPU = inv(C_on_CPU); % Invert the matrix

```

Listing 1: MATLAB CPU code that generates and inverts a matrix.

```

1 iRows = 1000; iColumns = 1000; % Number of rows and columns
2 C_on_GPU = gpuArray.randn(iRows, iColumns); % Generate random number on the GPU
3 InvC_on_GPU = inv(C_on_GPU); % Invert the matrix
4 InvC_on_CPU = gather(InvC_on_GPU); % Transfer the data from the GPU to CPU

```

Listing 2: MATLAB GPU code that generates and inverts a matrix.

that generates the random number with an underlying raw CUDA code. Once the variable `C_on_GPU` is created, standard functions such as `inv` recognize that the variable is on GPU memory and execute the corresponding GPU function, e.g., `inv` is executed directly on the GPU. This is completely transparent to the user. If further calculations are needed on the CPU, then the command `gather` transfers the data from GPU to the CPU, see Line 3 of Listing 2. A lot of supported functions already exist and this number is continuously increasing with new MATLAB releases.

3.2. Parallel sequential Monte Carlo

The structure of the GPU program, which is similar to the CPU one, is reported in Appendix A. In a graphical context the majority of the computations are executed in single precision floating point, so GPUs were initially optimized to perform these types of computations. Lately, GPUs have been extended to double precision calculation, see Section 4. Since a GPU performs a relatively small set of operations on a specific set of data points (each vertex on the screen), GPU makers (e.g., NVIDIA and ATI) focus mainly on creating hardware that specializes in these tasks instead of a wide array of operations such as the CPU. Therefore, the set of problems in which the GPU can be used is restricted, but GPU performs the specialized tasks more efficiently than the CPU. For example, matrix multiplication and, in general, matrix linear algebra are highly parallelizable problems and these operations are very suitable for GPGPU computing because they can be easily divided into the large number of cores available on the GPU, see Gregory and Miller (2012) for an introduction.

At first sight our problem does not seem to be easily parallelizable. But a closer look shows that the only sequential part of the algorithm is the time iteration, indeed the results of time $t + 1$ are dependent on the results of time t . Our key idea is to rewrite in matrix form that part of the algorithm that iterates over particles and predictive draws in order to exploit the GPGPU computational efficiency. Following the notation in Section 2, we let M be the number of draws from the predictive densities, K the number of predictive models, L the number of variables to predict, T the time horizon, and N the number of particles. Consider $L = 1$ for the sake of simplicity, then the code carries out a matrix of dimension $(MN \times K)$. The dimension could be large, e.g., in our simulation and empirical experiments it is $(5,000 \cdot 1,000 \times 3)$ and $(1,000 \cdot 1,000 \times 12)$ respectively. All the operations, such as addition and multiplication, become just matrix operations that the GPU is explicitly designed for.

As an example of such a coding strategy, we describe the parallel version of the initialization step of the SMC algorithm (see first step of the diagram in Appendix A and in *Step 0* in Section 2). We apply a linear regression and then generate a set of normal random numbers to set the initial values of the states. Using a multivariate approach to the regression problem, we can perform it in just one single, big matrix multiplication and inversion for all draws. An example of initialization, similar to the one used in the package, is given in Listing 3.³

Listing 3 shows that the predictive densities and the observable variables are stacked in block-diagonal matrices (Lines 1–8) of dimensions $(TM \times MK)$ and $(TM \times M)$ by using the command `blkdiag`, and then transferred to the GPU by the `gpuArray` command (Lines 10–11). Line 13 carries out the multivariate regression, the function `gpuArray.randn` is then used to generate normal random numbers on the GPU and thus to initialize the value of the

³In the package, we use the following labeling: `Setting.iDimOmega` for K , `Setting.iDraws` for M and `Setting.cN` for N .

```

1 %% Initialization of the matrix %%
2 mX = []; mY = [];
3 for j=1:M
4     %% Build the block-diagonal matrix over the draws %%
5     mX = blkdiag(mX, mXAll(:, :, j));
6     %% Repeat the vY matrix for multivariate regression %%
7     mY = blkdiag(mY, vY);
8 end
9 %% Load data on the GPU memory %%
10 mXGPU = gpuArray(mX);
11 mYGPU = gpuArray(mY);
12 %% Initialize particles on the GPU %%
13 mOmega = (mXGPU\mYGPU); %% Multivariate regression %%
14 mMatrix = KronBsxfun(gpuArray.ones(M, 1), gpuArray.eye(K));
15 mOmega = mOmega' * mMatrix;
16 mOmega = KronBsxfun(gpuArray.ones(N, 1), mOmega) + 5 * gpuArray.randn(N * M
    , K);

```

Listing 3: Block regression on the GPU.

```

1 mOmega = mOmega' + KronBsxfun(gpuArray.ones(1, M * N), sqrt(Sigma)).*
    gpuArray.randn(K, M * N);

```

Listing 4: Draws for the latent states.

particles (Lines 14–17).

This strategy is carried out all over the program and also applied to the simulation of the set of particles. For example, Listing 4 reports a sample of the code for the SMC prediction step (see [Step 2.a](#) in Section 2) for the latent states.

The Kronecker product (function `KronBsxfun`) creates a suitable matrix of standard deviations. We notice that the matrix implementation of the filter requires availability of physical memory on the graphics card. If there is not enough memory to run all the draws in parallel, then it is possible to split the M draws in $k = \frac{M}{m}$ blocks of size m and to run the combination algorithm sequentially over the blocks and in parallel within the blocks.⁴

The only step of the algorithm which uses the CPU is resampling (see diagram in Appendix A and [Step 2.d](#) in Section 2). The generated particles are copied to the CPU memory and, after the necessary calculations, they are passed back to the GPU. Some comments are in order. We use the resampling on CPU because it is not easily parallelizable. Although propagation and weighing steps are easy to parallelize (we work on different particles separately), the resampling step requires collective operations across particle weights and those operations are not easily to parallelize. Parallelizing the resampling step with a new and more efficient algorithm is an active field of research, see among others [Murray, Lee, and Jacob \(2014\)](#) and the reference therein, but this is beyond the scope of this paper. Moreover, this copying back and forth introduces a relatively high computational cost in small problems, but becomes much less important as the number of particles and series increases.

⁴We run the blocks sequentially because MATLAB does not yet have a parallel for loop command for running in parallel the $k = \frac{M}{m}$ blocks of GPU computations. The **DeCo** parallel CPU version sets $m = 1$ and parallelizes over the $k = M$ blocks.

4. Differences between CPU and GPU

GPUs can execute calculations in single and double precision as defined by the IEEE 754 standard (IEEE Computer Science 2008). Single precision numbers are half the size of double precision numbers and they are more limited in the range of values represented. If an application requires a high degree of precision, double precision numbers are the only possibility. We work with double precision numbers because our applications focus on density forecasting and precise estimates of statistical quantities, such as extreme events that are in the tails of the predictive distribution, may be very important for economic and financial decisions.

The GPU cards are very fast in single precision calculation, but loose power in double precision. Therefore, some parameters should be set carefully to have a fair comparison between CPU and GPU. First, both programs have to be implemented in double precision. Second, the CPU program has to be in parallel in order to use all available CPU cores. Third, the choice of the hardware is crucial, see Aldrich (2013) for a discussion. In all our experiments, we use a recent CPU processor, Intel Core i7-3820QM, launched in 2012Q2. This CPU has four physical cores that doubled thanks to Hyper-Threading Technology. Not all users of package **DeCo** might have access to such up-to-date hardware given its costs. So we also run the CPU code using a less expensive machine, the Intel Xeon X3430, launched in 2009Q3. To run the CPU code in parallel, MATLAB requires the parallel computing toolbox. We also investigate performance when this option is switched off and the CPU code is run sequentially.

The GPU used in this study is a NVIDIA Quadro K2000M. The card is available at a low cost, but it also has low performance because it is designed for a mobile machine (as indicated by the suffix M). A user with a desktop computer might have access to a more powerful video card, such as, e.g., NVIDIA Tesla. We refer to MATLAB for GPU comparisons and, in particular, to the function `GPUBench` freely available at <http://www.mathworks.co.uk/matlabcentral/fileexchange/34080-gpubench>.

Finally we emphasize that the results of the CPU and GPU versions of our combination scheme are not necessarily identical. The parallelization is implemented differently in the two versions to fully exploit the GPU advantage in working with a large matrix, selected in the toolbox by the number of blocks of draws. The CPU is parallelized for each simulation. To investigate the numerical differences between CPU and GPU, we provide a numerical integration experiment based on standard Monte Carlo integration where we can compare numerical solutions when the random generator is fixed and when it is not. We also repeat some of the simulation exercises in BCRVD (2013).

4.1. Monte Carlo integration

We consider six simple integration problems and compare their analytical solutions to their crude Monte Carlo (see Robert and Casella 2004) numerical solutions. Let us consider the two integrals of the function f over the unit interval

$$\mu(f) = \int_0^1 f(x)dx, \quad \sigma^2(f) = \int_0^1 (f(x) - \mu(f))^2 dx.$$

The Monte Carlo approximations of the integrals are

$$\hat{\mu}_N(f) = \frac{1}{N} \sum_{i=1}^N f(X_i), \quad \hat{\sigma}_N^2(f) = \frac{1}{N} \sum_{i=1}^N (f(X_i) - \hat{\mu}_N(f))^2,$$

Figure 1: CDFs of the CPU and GPU mean square errors in the MC estimators of $\mu_N(f)$, $N = 1500$, when setting the same random generator number (left column) and when not (right column), for different choices of f (first row: $f(x) = x$; second row: $f(x) = x^2$; third row: $f(x) = \cos(\pi x)$), using $G = 1000$ replications.

Figure 2: CDFs of the CPU and GPU mean square errors in the MC estimators of $\hat{\sigma}_N^2(f)$ when setting the same random generator number (left column) and when not (right column), for different choices of f (different rows), using $G = 1000$ replications.

where X_1, \dots, X_N is a sequence of N i.i.d. samples from a standard uniform distribution.

The numerical integration problems considered in the experiments correspond to the following choices of the integrand function:

1. $f(x) = x$;
2. $f(x) = x^2$;
3. $f(x) = \cos(\pi x)$.

We repeat $G = 1000$ times each Monte Carlo integration experiment with sample sizes $N = 1500$. Figures 1 and 2 show the CPU and GPU cumulative distribution functions (CDFs) of

the mean square errors when the random generator number is fixed to be equal for the two methods and when it is not. The two CDFs are basically identical when the random generator is fixed, with a difference at the 17th decimal. The differences are larger when the seed is not fixed, but still very small. Moreover, positive and negative values are equally distributed indicating that there is no evidence of higher precision of one of the two methods. We also test the statistical relevance of the differences between CPU and GPU and run a two-sample Kolmogorov-Smirnov test on the CDF of the CPU and GPU squared errors. The results of the tests show that the null hypothesis that CPU and GPU squared errors come from the same distribution cannot be rejected. Thus, we conclude that CPU and GPU also give equivalent results from a statistical point of view even when the random generator number is not set at the same value in the CPU and GPU algorithm. This leads us to move on to the simulation exercises in BCRVD (2013).

4.2. Simulation exercises

Following BCRVD (2013) we compare the cases of unbiased and biased predictors and of complete and incomplete model sets using the **DeCo** code. We assume the true model is $\mathcal{M}_1 : y_{1,t} = 0.1 + 0.6y_{1,t-1} + \varepsilon_{1,t}$ with $\varepsilon_{1,t} \stackrel{\text{i.i.d.}}{\sim} \mathcal{N}(0, \sigma^2)$, $t = 1, \dots, T$, $y_{1,0} = 0.25$, $\sigma = 0.05$ and consider four experiments. We apply the **DeCo** package and use the GUI described in Appendix B to provide the inputs to the combination procedure. We follow BCRVD (2013) and assume that θ is given.⁵

Complete and incomplete model set experiments

Complete model set experiments: We assume the true model \mathcal{M}_1 belongs to the set of models in the combination. In the first experiment the model set also includes two biased predictors: $\mathcal{M}_2 : y_{2,t} = 0.3 + 0.2y_{2,t-2} + \varepsilon_{2,t}$ and $\mathcal{M}_3 : y_{3,t} = 0.5 + 0.1y_{3,t-1} + \varepsilon_{3,t}$, with $\varepsilon_{it} \stackrel{\text{i.i.d.}}{\sim} \mathcal{N}(0, \sigma^2)$, $t = 1, \dots, T$, $i = 2, 3$. In the second experiment the complete model set also includes two unbiased predictors: $\mathcal{M}_2 : y_{2,t} = 0.125 + 0.5y_{2,t-2} + \varepsilon_{2,t}$ and $\mathcal{M}_3 : y_{3,t} = 0.2 + 0.2y_{3,t-1} + \varepsilon_{3,t}$, with $\varepsilon_{it} \stackrel{\text{i.i.d.}}{\sim} \mathcal{N}(0, \sigma^2)$, $t = 1, \dots, T$, $i = 2, 3$.

Incomplete model set experiments: We assume the true model is not in the model set. In the third experiment the model set includes two biased predictors: $\mathcal{M}_2 : y_{2,t} = 0.3 + 0.2y_{2,t-2} + \varepsilon_{2,t}$ and $\mathcal{M}_3 : y_{3,t} = 0.5 + 0.1y_{3,t-1} + \varepsilon_{3,t}$, with $\varepsilon_{it} \stackrel{\text{i.i.d.}}{\sim} \mathcal{N}(0, \sigma^2)$, $t = 1, \dots, T$, $i = 2, 3$. In the fourth experiment the model set includes unbiased predictors: $\mathcal{M}_2 : y_{2,t} = 0.125 + 0.5y_{2,t-2} + \varepsilon_{2,t}$, $\mathcal{M}_3 : y_{3,t} = 0.2 + 0.2y_{3,t-1} + \varepsilon_{3,t}$, with $\varepsilon_{it} \stackrel{\text{i.i.d.}}{\sim} \mathcal{N}(0, \sigma^2)$, $t = 1, \dots, T$, $i = 2, 3$.

We develop the comparison experiments with both 1000 and 5000 particles. Table 2 reports the time comparison (in seconds) to produce forecast combinations for the different experiments and different implementations. Parallel implementation on GPU NVIDIA Quadro K2000M is the most efficient, in terms of computing time, for all experiments. Time differences between the CPU and GPU executions are very large (see Table 2, Panel (a)), and result in a saving of up to several hours when using 5000 particles (see Table 2, Panel (b)).

⁵We use the exact same values for the various parameters as in BCRVD (2013) which are not necessarily the same as the default values in the toolbox. See BCRVD (2013) and the replication files for further details.

Table 2: Density combination computing time in seconds. Rows: different simulation experiments. Columns: parallel GPU (p-GPU) and parallel CPU (p-CPU-i7) implementations on GPU NVIDIA Quadro K2000M with CPU Intel Core i7-3820QM, 3.7GHz; parallel CPU (p-CPU-Xeon) and sequential CPU (CPU-Xeon) implementations on Intel Xeon X3430 4core, 2.40GHz. In parentheses: efficiency gain in terms of CPU/GPU times ratio.

More specifically, the computational gain of the GPU implementation over parallel CPU implementation varies from 3 to 4 times for the Intel Core i7 and from 5 to 7 times for the Intel Xeon X3430. The overperformance of the parallel GPU implementation on sequential CPU implementation varies from 15 to 20 times when considering an Intel Xeon X3430 machine as a benchmark.

Figure 3 compares the weights for experiments 1 and 2. The weights follow a very similar pattern, but there are some minor discrepancies between them for some observations. Differences are larger for the median value than for the smaller and larger quantiles. The differences are, however, smaller and almost vanish when one focuses on the predictive densities in Figure 4, which is the most important output of the density combination algorithm. We interpret the results as evidence of no interpretational and statistical significance of the differences between CPU and GPU draws.

The results are similar when focusing on the incomplete model set in Figures 5–6. The evidence does not change when we use 5000 particles.

Figure 3: GPU and CPU 1000 particles filtered model probability weights for the complete model set. Median and 95% credibility region for model weights 1, 2 and 3 (different rows).

Figure 4: GPU and CPU 1000 particles filtered density forecasts for the complete model set. Mean and 95% credibility region of the combined predictive density.

Learning mechanism experiments

BCRVD (2013) document that a learning mechanism in the weights is crucial to identify the true model (in the case of complete model set) or the best model (in the case of incomplete model set) when the predictions are unbiased, see also left panels in Figures 3–5. We repeat the two unbiased predictor experiments and introduce learning in the combination weights as discussed in Section 2. We set the learning parameters $\lambda = 0.95$ and $\tau = 9$. Table 3 reports the time comparison (in seconds) when using 1000 and 5000 particles filtered model probability weights. The computation time for **DeCo** increases when learning mechanisms are applied, in particular for the CPU. The GPU is 10% to 50% slower than without learning, but CPU is 2.5 to almost 4 times slower than previously. The GPU/CPU ratio, therefore, increases in favor of GPU with GPU computation 5 to 70 times faster depending on the alternative

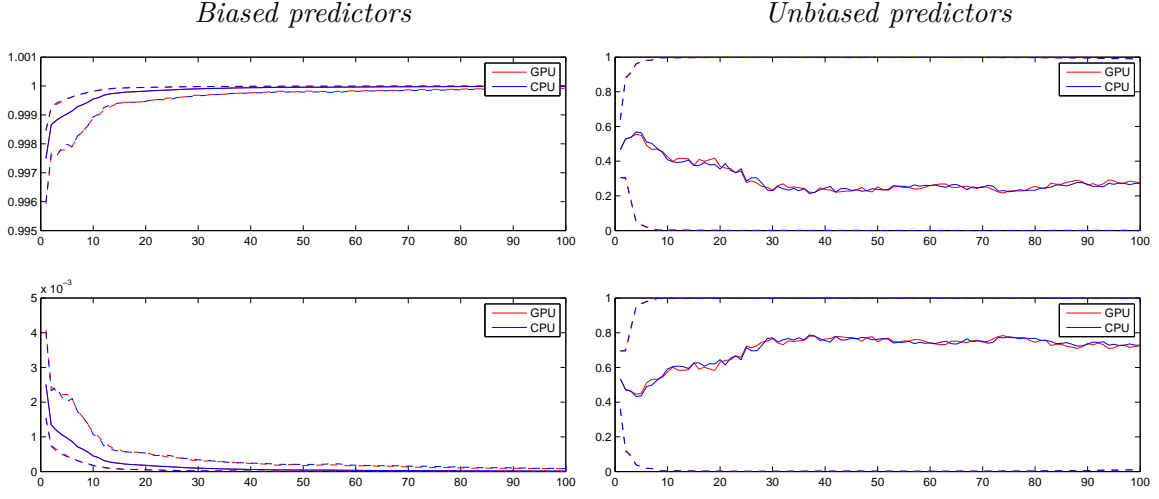

Figure 5: GPU and CPU 1000 particles filtered model probability weights for the incomplete model set. Median and 95% credibility region for model weights 1, 2 and 3 (different rows).

Figure 6: GPU and CPU 1000 particles filtered density forecasts for the incomplete model set. Mean and 95% credibility region of the combined predictive densities.

CPU machine considered. The **DeCo** codes with learning have some `if` commands related to the minimum numbers of observations necessary to initiate the learning, which increases computational time substantially. The parallelization in GPU is more efficient because it is carried out on blocks of draws and these `if` commands play a minor role. We expect that the gain might increase to several hundreds of times when using parallelization on GPU clusters.

5. Empirical application

As a further check of the performance of the **DeCo** code, we compare the CPU and GPU versions for the macroeconomic application developed in BCRVD (2013). We consider $K = 6$ time series models to predict US GDP growth and PCE inflation: a univariate autoregressive

<i>(a) 1000 particles</i>				
	p-GPU	p-CPU-i7	p-CPU-Xeon	CPU-Xeon

Incomplete Model Set	7260	35292 (4.86)	73256 (10.09)	274301 (37.78)

Table 3: Density combination computing time in seconds. Rows: different simulation experiments with unbiased predictors and a learning mechanism in the weights. Columns: parallel GPU (p-GPU) and parallel CPU (p-CPU-i7) implementations on GPU NVIDIA Quadro K2000M with CPU Intel Core i7-3820QM, 3.7GHz; parallel CPU (p-CPU-Xeon) and sequential CPU (CPU-Xeon) implementations on Intel Xeon X3430 4core, 2.40GHz. In parentheses: efficiency gain in terms of CPU/GPU times ratio.

model of order one (AR); a bivariate vector autoregressive model for GDP and PCE of order one (VAR); a two-state Markov-switching autoregressive model of order one (ARMS); a two-state Markov-switching vector autoregressive model of order one for GDP and inflation (VARMS); a time-varying autoregressive model with stochastic volatility (TVPARSV); and a time-varying vector autoregressive model with stochastic volatility (TVPVARSV). Therefore, the model set includes constant parameter univariate and multivariate specifications; univariate and multivariate models with discrete breaks (Markov-Switching specifications); and univariate and multivariate models with continuous breaks. These are typical models applied in macroeconomic forecasting; see, for example, [Clark and Ravazzolo \(2015\)](#), [Korobilis \(2013\)](#) and [D’Agostino, Gambetti, and Giannone \(2013\)](#).

We evaluate the two combination methods by applying the following evaluation metrics: root mean square prediction errors (RMSPE), Kullback Leibler information criterion (KLIC) based measure, the expected difference in the logarithmic scores (LS) and the continuous rank probability score (CRPS). Accuracy statistics and related tests (see BCRVD 2013) are used to compare the forecast accuracy.

Table 4 reports results for the multivariate combination approach. For the sake of brevity, we just present results using parallel GPU and the best parallel CPU Intel Core i7-3820QM machine. We also do not consider a learning mechanism in the weights. GPU is substantially faster, almost 5.5 times faster than CPU, reducing the computational time by more than 5000 seconds. GPU therefore performs relatively better in this experiment than in the previous simulation experiments (without learning mechanisms). This can be explained by the larger set of models and the multivariate application. The number of simulations has increased substantially and CPU starts to hit physical limits, slowing down the computation and increasing time. GPU has no binding limits and just doubles the time of simulation experiments with

	GDP		Inflation	
	GPU	CPU	GPU	CPU
Time	1249	6923	–	–
RMSPE	0.634	0.637	0.255	0.256
CW	0.000	0.000	0.000	0.000
LS	−1.126	−1.130	0.251	0.257
p value	0.006	0.005	0.021	0.022
CRPS	0.312	0.313	0.112	0.112
p value	0.000	0.000	0.000	0.000

Table 4: Computing time and forecast accuracy for the macro-economic application for the GPU (column GPU) and CPU (column CPU) implementations. Rows: Time: time to run the experiment in seconds; RMSPE: root mean square prediction error; CW: p value of the [Clark and West \(2007\)](#) test; LS: average logarithmic score over the evaluation period; CRPS: cumulative rank probability score; LS p value and CRPS p value: [Harvey *et al.* \(1997\)](#) type of test for LS and CRPS differentials respectively.

a univariate series and the same number of draws and particles.⁶ This suggests that GPU might be an efficient methodology to investigate when averaging large sets of models.

Accuracy results for CPU and GPU combinations are very similar and just differ after the third decimal, confirming previous intuitions that the two methods are not necessarily numerically identical, but provide identical economical and statistical conclusions.⁷ The combination approach is statistically superior to the AR benchmark for all the three accuracy measures we implement.

6. Conclusion

This paper introduces the MATLAB package **DeCo** (density combination) based on parallel sequential Monte Carlo simulations to combine density forecasts with time-varying weights and different choices of scoring rule.

The package is easy to use for a standard MATLAB user and to facilitate promulgation we have implemented a GUI, which just requires a few input parameters. The package takes full advantage of recent computer hardware progresses and uses banks of parallel SMC algorithms for the density combination using both multi-core CPU and GPU implementation.

The **DeCo** GPU version is up to 70 times faster than the CPU version and even more for larger sets of models. More specifically, our simulation and empirical experiments were conducted using a commercial notebook with CPU Intel Core i7-3820QM and GPU NVIDIA Quadro K2000M, and MATLAB 2013b version, and show that the **DeCo** GPU version is faster than the parallel CPU version, up to 10 times when the weights include a learning mechanism and up to 5.5 times without it, when using an i7 CPU machine and the parallel computing toolbox. These findings are similar to results in [Brodtkorb *et al.* \(2013\)](#) when using a raw CUDA

⁶Unreported results show that GPU is more than 36 times faster than sequential CPU implementation on Intel Xeon X3430 4core.

⁷Numbers for the CPU combination differ marginally (and often just in the third decimal) from those in Table 4 in [BCRVD \(2013\)](#) due to the use of a different MATLAB version, different generator numbers and parallel tooling functions.

environment. In the comparison between GPU and non-parallel CPU implementations, the differences between GPU and CPU time increase up to almost 70 times when using a standard CPU processor, such as quad-core Xeon. Our results can be further improved with the use of more powerful graphics cards, such as GTX cards. All comparisons have been implemented using double precision for both the CPU and GPU versions. However, if an application allows for a lower degree of precision, then single precision calculation can be used and massive gains (up to 500) can be attained, as documented in [Lee *et al.* \(2010\)](#) and [Durham and Geweke \(2014\)](#).

We also document that the CPU and GPU versions do not necessarily provide the exact same numerical solutions to our problems, but differences are not economically and statistically significant. Therefore, users of **DeCo** might choose between the CPU and GPU versions depending on the available and preferred computing clusters.

Finally, we expect that our research and the **DeCo** GPU implementation would benefit enormously from improvement in the MATLAB parallel computing toolbox, such as the possible incorporation of a parallel “for” loop command for GPU; by the inclusion in the package of different particle filters, such as post- and pre-regularized particle filters and of different density combination schemes; and by applications to large sets of predictive densities as in [Casarin, Grassi, Ravazzolo, and van Dijk \(2015\)](#).

A. Flow-chart of GPU DeCo package

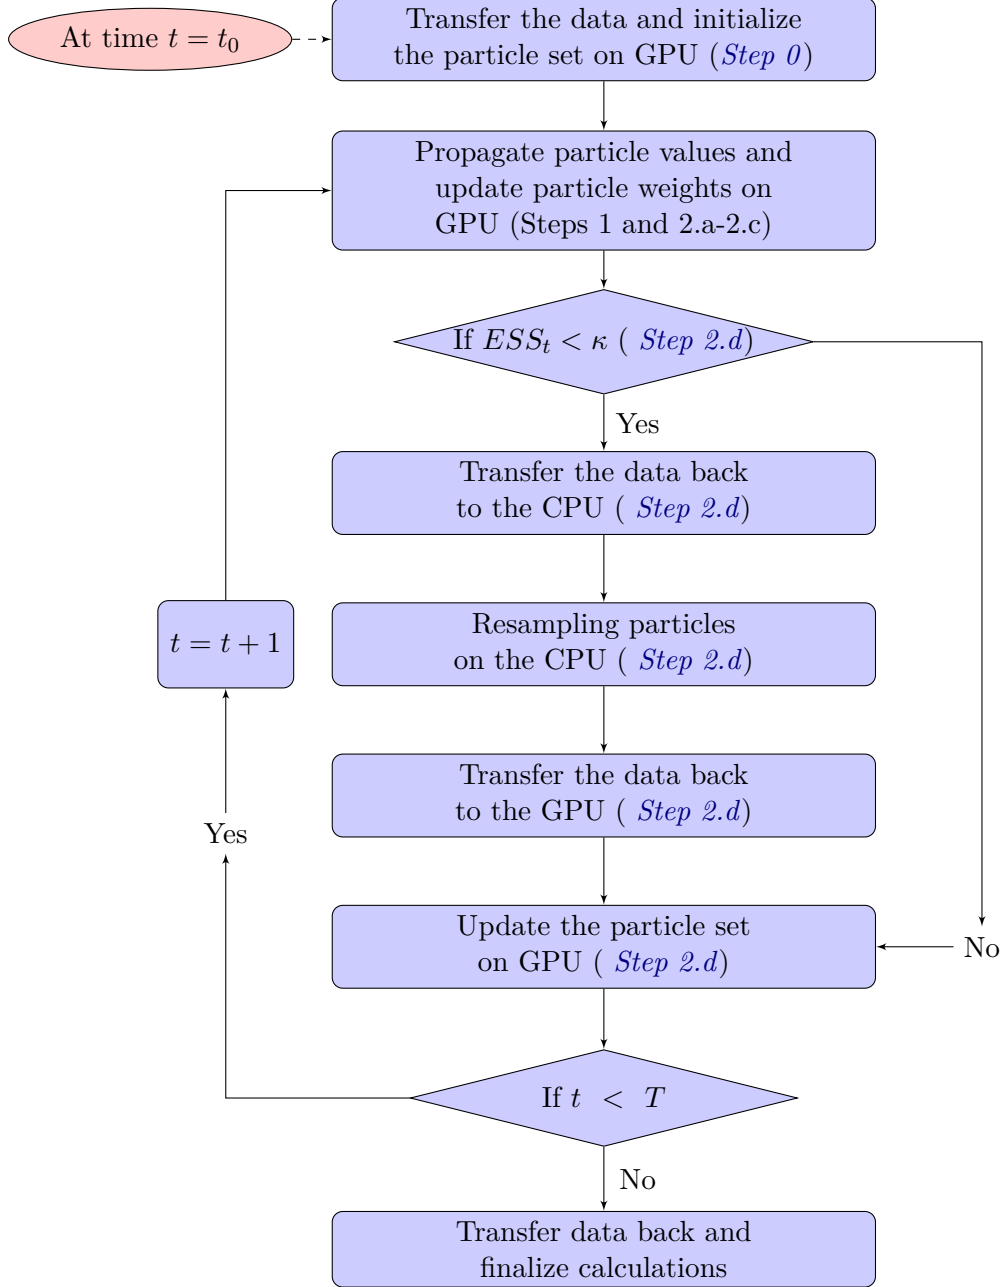

Figure 7: Flow chart of the parallel SMC filter given in Section 2.

B. The GUI

Figure 8 shows the GUI of the **DeCo** package, which contains all the necessary inputs for our program. The list box loads and displays the available dataset in the directory **Dataset**. The figure shows, as example, the dataset **Total_long.mat**. The directory **Dataset** also contains

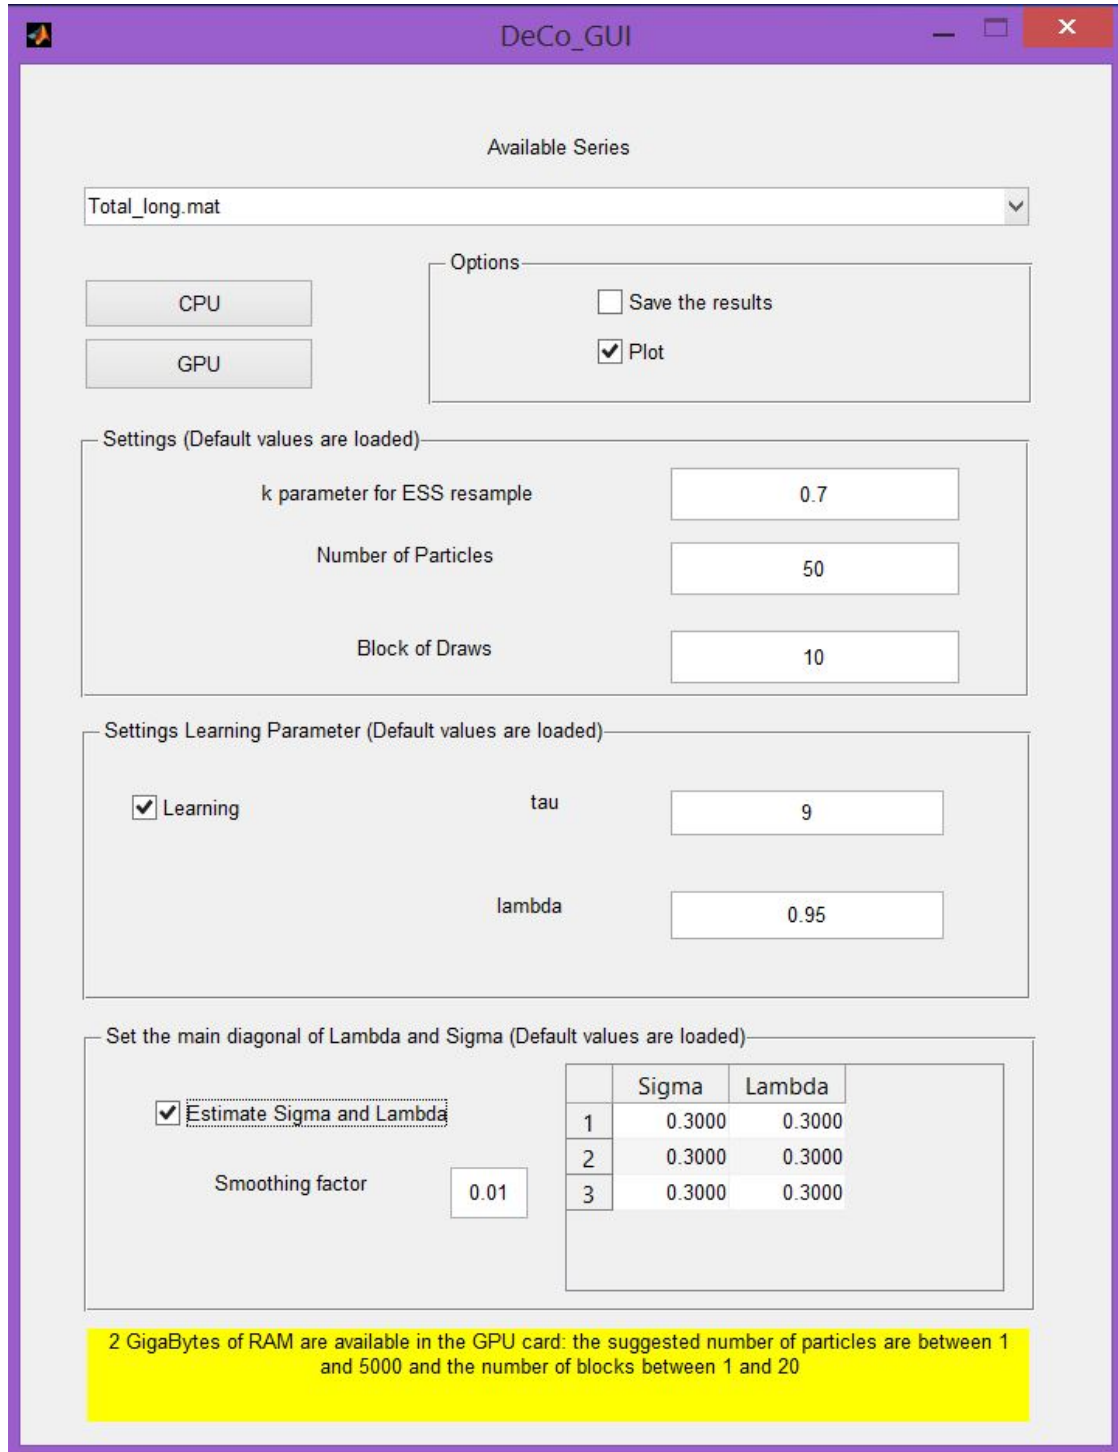

Figure 8: The GUI of the **DeCo** package, case of GPU available.

two other datasets of different dimensions. The three databases differ in sample size, number of predictive series and number of series to be predicted.

The panel **Options** contains the command for saving and plotting the results. The results are

Figure 9: The GUI of the **DeCo** package, case of no GPU available.

saved in the directory `OutputCPU` or `OutputGPU` depending on the type of calculation chosen. The panel **Settings** contains the selection of the number of particles, the number of blocks of draws (see Section 3.2) and the resampling threshold κ . All three options have default values that are also reported. The number of block of draws is only relevant for the GPU version. The panel **Setting Learning Parameter** allows the user to perform the calculation with or without learning in the weights, see Section 4.2. When the option **Learning** is chosen, the

edit box allows the learning parameter to be set, the default values are $\lambda = 0.95$ and $\tau = 9$.

The panel **Set the main diagonal of Lambda and Sigma** reports an editable table that allows the values for **Sigma** and **Lambda** to be set (default values are loaded). The check box **Estimate Sigma and Lambda** allows the estimation of the **Sigma** and **Lambda** matrix. Once the option is selected, the editable table reports the mean values of the priors and the user also has to select the variance of the shocks (smoothing factor) for those matrices. A default value of 0.01 is set.

Finally the button **CPU** starts the corresponding CPU program and the button **GPU** executes the program on the GPU. In the case of no GPU card available, the corresponding button and the edit box **Blocks of Draws** are not visible, see Figure 9 using as example the dataset **Total_medium.mat**.

Some considerations are in order. First, the CPU is already implemented in parallel form and the user has to start a parallel session in MATLAB by typing the command `matlabpool open` in the MATLAB main window. Please refer to MATLAB online help and to the toolbox description. Second, the dataset accepted by the program is the **mat** format and has the following structure. It includes two variables, the first one is defined as vY and it contains a $(T \times L)$ matrix of the variables $\{y_t\}_{t=1}^T$ to be predicted, where T is the number of 1-step ahead forecasts and L the size of observable variables to forecast. The second one is a $4 - D$ matrix defined mX with the following dimensions (T, M, L, KL) , where M is the size of i.i.d. samples from the predictive densities, and KL the number of 1-step ahead predictive densities. See Appendix C for a discussion of default values. Finally, the user might apply different learning mechanisms based on other scoring functions than the one applied and discussed in Section 2. In order to do this, the user should change the functions in the files `PFCoreCPU.m` and `PFCoreGPU.m`.

C. The MATLAB functions

As an alternative to the GUI interface, one can use the two functions `DeCo_CPU` and `DeCo_GPU` for density combination on CPU and GPU, respectively. Both functions have as required input the name of the **mat** file, which contains the dataset. The dataset must be placed in the directory **Dataset** and must have the structure described in Appendix B. The two functions have some optional input parameters, which are described in Table 5. The default values are the same for the functions `DeCo_CPU` and `DeCo_GPU`. The number of block of draws is only relevant for the GPU version and depends on the size of the RAM of the GPU card. Table 6 suggests a set of values for different sizes of the GPU card assuming that the number of draws from the different individual predictive densities is 1000. The default value of the number of particles is set to 50, which is useful to have an indication on how the code runs and what findings to expect. Anyway, we believe they are too few to produce precise results. Table 6 also suggests a set of values for this parameter for different sizes of the GPU card. The same values can be used for the CPU version. In this case larger number of particles increases substantially the computational time but does not require any optimization for the number of blocks of draws.

If the user would like to combine the densities in the dataset **Total_short.mat**, without using learning in the weights, without estimating the combination parameters Λ and Σ , and setting the number of particles to $N = 1000$ and the number of blocks to 20, then the following

Optional parameters	Type	Default value	Description
'Learning'	Integer	0	If 0 the combination is without learning. If 1 the combination is with learning.
'Estimate'	Integer	0	If 0 the value of parameters Λ and Σ . provided by the user will be used. If 1 the parameters Λ and Σ are estimated.
'Plot'	Integer	1	If 0 no graphical output is returned. If 1 a graphical output is returned.
'Save'	Integer	1	If 0 the output is not saved. If 1 the output is saved.
'Tau'	Integer	9	Learning parameter $\tau > 0$.
'lambda'	Numeric	0.95	Learning parameter $\lambda \in (0, 1)$.
'Lambda'	Numeric	0.3	Elements of the main diagonal of Λ . Its value must be positive.
'Kappa'	Numeric	0.7	ESS resampling threshold $\kappa > 0$.
'Var'	Numeric	0.01	Smoothing factor $h > 0$.
'N'	Integer	50	Number of particles $N > 0$.
'Draws'	Integer	10	Number of blocks of draws.

Table 5: Optional input parameters for the CPU and the GPU implementations.

Optional parameters	Type	Default value	GPU card's RAM	Description
'Draws'	Integer	10	1 GigaBytes	Number of blocks of draws, $k = M/m$, $k > 0$.
		20	2 GigaBytes	
		100	> 2 GigaBytes	
'N'	Integer	1000	1 GigaBytes	Number of particles N , with $N > 0$.
		5000	2 GigaBytes	
		10000	> 2 GigaBytes	

Table 6: Optional input parameter numbers of blocks, $k = M/m$, and particles for the GPU code.

command can be typed at the MATLAB command line

```
DeCo_GPU('Total_short.mat', 'N', 1000, 'Draws', 20)
```

A user interested in combining the densities and estimating the Λ and Σ parameters can modified the previous command as follows

```
DeCo_GPU('Total_short.mat', 'N', 1000, 'Draws', 20, 'Estimate', 1,  
         'Var', 0.01)
```

where we set to 0.01 the smoothing factor h of the regularisation step of the particle filter.
